

# BUG REACTOR SIMULATION

Using VP Link to simulate a continuous fermenter

## Abstract

There are a number of interesting control problems with this process. .

Winston JENKS  
winston.jenks@woodplc.com

The process is shown below. The goal of the continuous fermenter is to avoid the time consuming operations of the batch reactor including deinventory, charging, and sterilization. In the continuous fermenter food for the bugs is sterilized continuously before being fed to the fermenter. This has a set of complications that arise due to the dead time introduced by the sterilization loop. In addition, the optimum residence time for the fermenter is dependent on the growth rate of the bugs in the fermenter. If the feed rate is too fast and the residence time is too short, then the bugs can be flushed out of the reactor before they have time to multiply. If the residence time is too long, then the bugs will be starved for food and their growth rate will be lower than the optimum. Ideally, the steady state is such that the production rate out the bottom of the reactor is such that bugs are removed from the fermenter as fast as they are growing. The trick is, knowing how fast they are growing is hard to measure.

This process generally starts with a fermenter that has been filled with sterilized media including some concentration of food. Bugs are introduced into the reactor, start to eat the food and multiply. The quantity of bugs in the reactor grows at an exponential rate, as the rate at which new bugs appear is proportional to the number of bugs in the reactor. Actually the growth rate is dependent on how “happy” the bugs are in their environment. Bugs grow at the maximum rate at a certain temperature and pH (and if we want to make it more complicated, dissolved oxygen level), as long as there is sufficient food. An excess of food does not make the bugs grow even faster, as there is some limit as to their metabolism. But a scarcity of food does reduce the growth rate and causes some bugs to die, meaning they will never reproduce again, even if the food supply is restored.

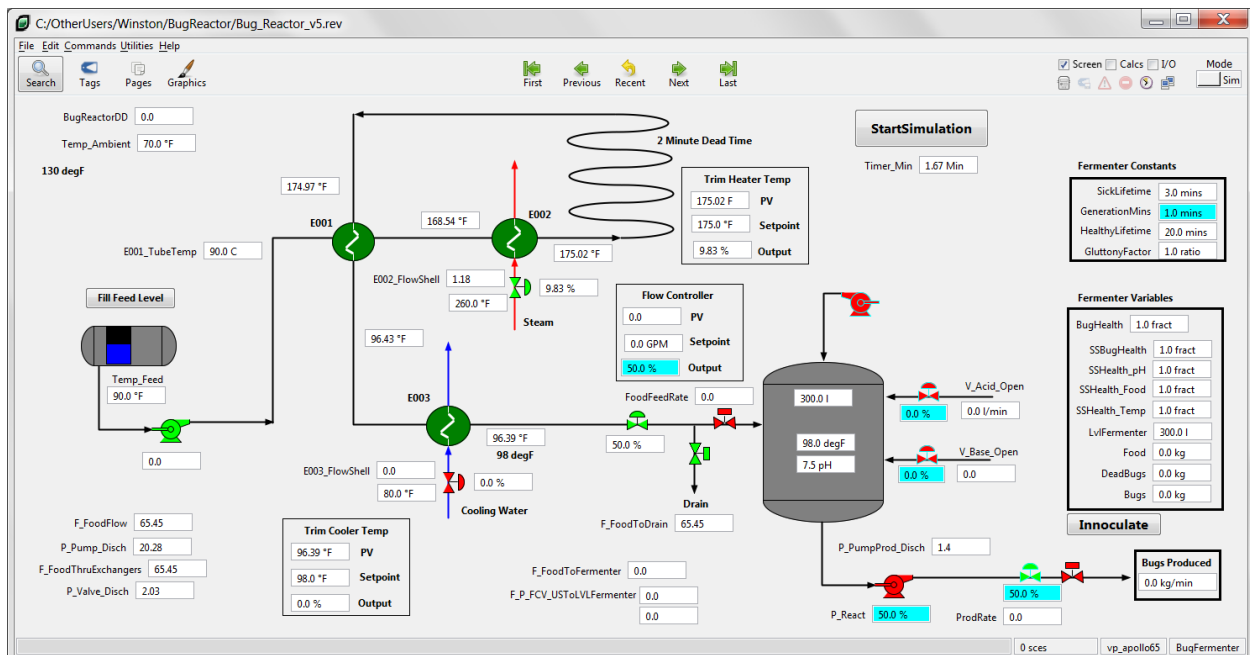

Figure 1 -- Process overview of the continuous fermenter

Here is what we know about the conditions in the bug reactor.

- Bugs grow exponentially in time when they are happy and have enough to eat.
- Bugs die. These bugs are still in the reactor (and will produce enzymes when they are sent downstream to be lysed). Dead bugs will never reproduce. Bugs can die because they are too old, or because conditions are not good, and they are no longer healthy. The farther the conditions are from optimum the fewer bugs remain healthy. Sick bugs die at a faster rate than healthy bugs.
- Bugs that are not healthy do not reproduce, but they could later if they get healthy again.
- Bugs like to be at 98 deg F.
- Bugs produce heat when they grow, so the fermenter must be cooled to maintain a steady temperature. The temperature controls do a pretty good job of controlling the fermenter temperature.
- Bugs like an environment where the pH is 7.5
- The food introduced to the reactor has a pH of 7.
- The waste product of growing bugs is basic, and as the bug growth rate increases, acid is required to maintain the pH at the proper level. You will see that the pH controls do a pretty good job.

Your job, Mr. Phelps, should you choose to accept it, is to feed the reactor at the optimum rate to maximize the bug yield. Bug yield is the totalized value of the production rate times the concentration of bugs in the effluent stream. As always, the author will disavow any knowledge of a relation to a real process.

You may also want to investigate how you can start up the sterilization loop as fast as possible, getting the food to the desired temperature for the appropriate length of time.

Other parts of the process that are important to know about.

The food needs to be pasteurized at 170 degrees F for at least two minutes. If the pasteurization criteria are not met, then invasive bugs from the outside world will be introduced into the fermenter and wipe out the laboratory bugs which are unprepared to compete with bugs that have adapted to live in the competitive life environment we call planet Earth. This means that all the laboratory bugs die, and the only option is to drain the fermenter, re-sterilize it, and start the process back up again. This is very costly.

If it is noticed that the food has not been sterilized, it can be diverted to the drain to avoid introducing it to the fermenter. While this can save the bugs in the fermenter, the bugs will go without the food supply for as long as it takes to resolve the sterilization issue and get the food going back to the fermenter.

The most likely piece of equipment to fail is the steam exchanger, E002, that does the final heating of the food to the pasteurization temperature. If the food is heated above 190 deg F, then the food (think of thinned molasses), will start to caramelize on the surface of the steam exchanger, causing it to foul and lose its effectiveness<sup>1</sup>.

---

<sup>1</sup> In the previous century, the author mis-operated this steam exchanger to the point that in order to transfer enough heat to the food through the fouled exchanger, the temperature controller increased the the steam temperature (and therefore pressure, as well) enough to blow the seals on the plate and frame exchanger. That was about a \$30,000 mistake (in 1986 dollars)--plus lost production. Oops.

Still to do:

- Adjust the pH by pooping bugs.
- Account for the heat that bugs produce while they live and eat.
- Add a cooling water valve to cool the fermenter.
- Add the section to this document that describes the model. Less for the brain design guy, but more for the eventual customer that is interested in how VP Link works to create their own models.
- Add controls for the automatic diversion of incompletely pasteurized food.
- Add description of the temperature vs. time dependence of the sterilization loop.
